ABSTRACT

Chronic kidney disease is a major risk factor for the incidence and severity of coronary artery disease. Patients with CKD present accelerated atherosclerosis and are prone to serious heart disease, including heart failure, before they ever reach dialysis. They have a worse cardiovascular (CV) prognosis than other patients after acute myocardial infarction (AMI), and after revascularisation.

The main aim of this review article is the presentation and discussion of the best available evidence on the use of statins in patients with hyperlipidaemia and CKD not on dialysis. This paper is not based on a systematic review of the best clinical evidence on the subject of statins and CKD. It is a scientific review based on recent studies (randomised controlled trials, systematic reviews and observational studies) on risk modulation with lipid-lowering drugs in CKD. The evidence on which this paper is based was identified by searching the best available secondary sources as well as primary databases if needed.

There are a series of statements that can be made on the effects of statins in patients with CKD not on dialysis. Firstly, the combination ezetimibe/simvastatin reduces AMI, non-haemorrhagic stroke and revascularisation in these patients, and a physician needs to treat less than 50 patients over four years to avoid a CV event. Secondly, the combination ezetimibe/simvastatin reduces LDL levels more than

simvastatin alone. Thirdly, treatment with atorvastatin plus ACE inhibitors or ARBs may reduce proteinuria and the rate of progression of kidney disease, proteinuria and hypercholesterolaemia. Fourthly, pravastatin was associated with slower renal function decline than placebo in patients with moderate reduced GFR and proteinuria. Fifthly, simvastatin has similar effects on total cholesterol, LDL and triglyceride in CKD patients as it has in patients with normal kidney function. Sixthly, statin use is associated with reduction in albuminuria or proteinuria. Seventhly, statin therapy with rosuvastatin reduced first cardiovascular events and all-cause mortality among men and women with low LDL, elevated CRP and moderate CKD. Finally, pravastatin may not be superior to usual care in preventing end-stage renal disease and addition of atorvastatin to angiotensin-converting enzyme inhibitor or angiotensin receptor blocker may slow progression of renal disease.

Key-Words:

Cardiac prognosis; chronic kidney disease; chronic renal disease; coronary artery disease; statins.

INTRODUCTION

Chronic kidney disease (CKD), also called chronic renal disease, is a major risk factor for the incidence and severity of coronary artery disease (CAD)¹. Cardiovascular (coronary) disease is the most frequent cause of death

among CKD patients and less than 2% of CKD patients eventually require renal replacement therapy².

Patients with CKD present accelerated atherosclerosis and are prone to serious heart disease (including heart failure) before they ever reach dialysis. They have a worse cardiovascular (CV) prognosis than other patients after acute myocardial infarction (AMI)³, and after revascularisation⁴.

Observational studies have shown that lowered glomerular filtration rate (GFR) and proteinuria are independent and major risk factors for CV disease⁵. In a recently published collaborative meta-analysis⁶, standardised data for all-cause and cardiovascular mortality were pooled to estimate hazard ratios (HRs) for all-cause and cardiovascular mortality associated with estimated glomerular filtration rate (eGFR) and albuminuria, adjusted for potential confounders.

The sample included 105,872 participants (730,577 person-years) from 14 studies with urine albumin-to-creatinine ratio (ACR) measurements showing that the risk of mortality was increased at lower eGFRs. That is, HRs were 1.18 (95% CI 1.05-1.32) for eGFR=60 mL/min/1.73 m², 1.57 (1.39-1.78) for 45 mL/min/1.73 m², and 3.14 (2.39-4.13) for 15 mL/min/1.73 m².

The sample also included 1,128,310 participants (4,732,110 person-years) from seven studies with urine protein dipstick measurements. The estimated glomerular filtration rate and ACR were associated also with risk of cardiovascular mortality, and in studies with dipstick measurements, proteinuria was an independent prognostic factor.

Treatment of CV risk factors in CKD patients – *i.e.* control of arterial hypertension, smoking cessation, weight loss and control of hyperglycaemia in diabetics and modulation of serum cholesterol – is of paramount prognostic importance, since they tend to significantly lower mortality (inconsistently) and morbidity in patients with renal failure⁷.

Prognosis of CKD patients with cardiac disease is poor. A recent retrospective analysis of 259 patients with CKD found that most of them had several cardiac risk factors⁸: hypertension in 87%, diabetes in 35%, cardiovascular disease in 40% and peripheral vascular disease in 14%. Forty-seven per cent of these patients were hospitalised after a median follow-up of 11.4

months. Cardiovascular disease (excluding congestive heart failure) or hypertension were the primary diagnoses in approximately 25% of these hospitalisations.

Until recently there was scanty evidence of the benefit of lipid-lowering therapy in patients with CKD, since CKD is generally an exclusion criterion for the trials modulating CV risk factors⁹. The only three published clinical trials in patients on dialysis (or post-kidney transplantation) using statins – atorvastatin¹⁰, rosuvastatin¹¹ and fluvastatin¹² – did not show a significant reduction in primary CV outcome, casting doubts on the benefit of this secondary preventive measure (since CKD is considered a CAD equivalent).

The same absence of benefit on mortality was seen on a recent meta-analysis⁷ which showed however that statin therapy significantly reduced lipid concentrations in patients with chronic kidney disease (all stages of disease). The results were total cholesterol (42 studies, 6,390 patients; WMD -42.28 mg/dl (1.10 mmol/l), 95% CI -47.25 to -37.32), and low density lipoprotein cholesterol (39 studies, 6,216 patients; -43.12 mg/dl (1.12 mmol/l), 95% CI -47.85 to -38.40) – and CV end points – proteinuria (g/24 hours) (6 trials, 311 patients; 95% CI -0.73 g/24 hour -0.95 to -0.52) – but no benefit on all-cause mortality (44 studies, 23,665 patients; 0.92, 95% CI 0.82 to 1.03). In this study no role of statins in primary prevention was established.

So the question seems to be: what is the real benefit of lipid-lowering therapy with statins in patients with CKD not on dialysis?

In this paper we briefly review the most recent scientific evidence on the use of statins in patients with chronic kidney disease not in dialysis, and the effect of therapy on clinical outcomes.

METHODOLOGY

- The main aim of this paper is the presentation and discussion of the best available evidence on the use of statins in patients with hyperlipidaemia and CKD not on dialysis. No specific subgroups were selected.
- This paper is not based on a systematic review of the best clinical evidence on the subject of

statins and CKD. It is a scientific review based on recent studies (randomised controlled trials, systematic reviews and observational studies) on risk modulation with lipid-lowering drugs in CKD.

- The evidence on which this paper is based was identified by searching the following secondary sources: Clinical Evidence, Essential Evidence Plus, Evidence Based Medicine, ACP Journal Club, UpToDate, Cochrane Library, DynaMed, NICE, Evidence Based Practice, Guideline International Network, National Guideline Clearinghouse, Essential Evidence Plus, ACP's PIER and Scottish Intercollegiate Guidelines Network.
- If the dates of the aforementioned sources were significantly outdated, Medline was searched also from the latest date to the present (December 2011).

LIPID ABNORMALITIES IN PATIENTS WITH CKD

The most common lipid abnormality in CKD patients is hypertriglyceridaemia, due to defective removal from the circulation and associated secondary hyperparathyroidism. Table I shows the alterations in lipid profiles in CKD¹³. In CKD patients total cholesterol concentration can be high (20-30% of patients), normal or low. HDL is normally low¹⁴, and plasma levels of lipoprotein(a) are usually elevated¹⁵.

Table I

Changes in lipids in CKD

Generally increased levels	Generally Decreased Levels
Triglycerides	Total cholesterol
Lipoprotein(a)	LDL cholesterol
Apoprotein B	HDL cholesterol
VLDL cholesterol	Apoprotein A1
IDL cholesterol	

In a recent paper¹⁶, researchers examined whether malnutrition or inflammation (M-I) would modify the relationship between cholesterol levels and CVD events in African-Americans with hypertensive CKD and a GFR between 20 and 65 ml/min per 1.73 m². 990 participants were stratified by the presence or absence of M-I (defined as body mass index \geq 23 kg/m² or C-reactive protein $>$ 10 mg/L at baseline). The primary composite outcome

included cardiovascular death or first hospitalisation for coronary artery disease, stroke, or congestive heart failure, occurring during a median follow-up of 77 months.

In adjusted analyses, the CVD composite outcome exhibited a significantly stronger relationship with total cholesterol for participants without M-I than for participants with M-I at baseline ($P<0.02$). In the non-M-I group, the cholesterol-adjusted hazard ratio (HR) for CVD increased progressively across cholesterol levels: HR = 1.19 [95% CI; 0.77, 1.84] and 2.18 [1.43, 3.33] in participants with cholesterol 200 to 239 and \geq 240 mg/dl, respectively. In the M-I group, the corresponding HRs did not vary significantly by cholesterol level. The authors concluded that the presence of M-I modifies the risk relationship between cholesterol level and CVD in African-Americans with hypertensive CKD.

Statins (3-Hydroxyl-3-methylglutaryl CoA reductase inhibitors) and other lipid-lowering drugs have been clearly demonstrated to diminish the morbidity and mortality of CV disease in the general population. Hence, there is hope that the use of these drugs may likewise help patients with CKD.

Also, it has been theorised that dyslipidaemia may contribute to the progression of CKD, so that lipid-lowering drugs may prove to slow CKD progression. The current medical literature provides insufficient data to guide the use of lipid-lowering drugs in the CKD population, in large part because CKD has been an exclusion criterion for most of the RCTs that have addressed this issue.

We selected clinical evidence on the effect of statins in patients with CKD and their benefit on a number of clinical outcomes.

TREATMENT OF CKD PATIENTS WITH STATINS

The effects of statin therapy on CKD patients were analysed in the ten studies below.

1. Bianchi S *et al.* trial, 2003¹⁷

In a prospective, controlled, open-label randomised trial, 56 patients with nondiabetic kidney disease

who were treated for one year with ACE inhibitors or ARB and other antihypertensives were randomised to atorvastatin (atorvastatin group) vs. no additional treatment (control group)¹⁷. After twelve months, urine protein excretion decreased in the atorvastatin group (from 2.2 to 1.2 g/24 hours, $P < 0.01$) and the control group showed no significant changes (from 2 to 1.8 g/24 hours, $P = \text{NS}$). Creatinine clearance did not decrease significantly in the experimental group (from 51 to 48.8 mL/minute) but decreased in the control (from 50 to 44.2 mL/minute). These results suggests that treatment with atorvastatin plus ACE inhibitors or ARBs may reduce proteinuria and the decline in renal function in patients with CKD, proteinuria, and hypercholesterolaemia, and the benefits appear to occur in addition to those of treatment with ACE inhibitor and ARBs alone.

■ 2. Post-hoc analysis of the CARE trial, 2003¹⁸

Another published study¹⁸ was a posthoc subgroup analysis of a randomised double-blind placebo controlled trial – the CARE trial²⁷ – to determine whether pravastatin reduced rates of loss of renal function in people with moderate CKD. In 690 patients (20.4% from 3,384 randomised patients) with eGFR < 60 mL/minute/1.73 m² (MDRD-GFR), no significant differences in rate of decline in eGFR comparing pravastatin vs. placebo was found (0.1 mL/min per 1.73 m²/yr slower; 95% CI -0.2 to 0.4; $P = 0.49$). Sub-subgroup analyses found that pravastatin was associated with slower renal function decline than placebo in patients with eGFR < 50 mL/minute/1.73 m² (difference 0.6 mL/minute/1.73 m²/year), eGFR < 40 mL/minute/1.73 m² (difference 2.5 mL/minute/1.73 m²/year) and proteinuria ($P = 0.006$). This result was not verified in another subgroup analysis of the ALLHAT trial²⁸.

■ 3. PREVEND-IT trial, 2004¹⁹

The Prevention of Renal and Vascular End-Stage Disease Intervention Trial (PREVEND IT)¹⁹, performed at a single Dutch centre, was a double-blind, randomised, placebo-controlled trial designed to assess whether lowering urinary albumin excretion would reduce cardiovascular events in low risk CKD (microalbuminuric subjects). The trial had a 2×2 factorial design involving fosinopril or placebo and pravastatin 40 mg or placebo. Patients (n=864, from a previous

cohort) were 28 to 75 years of age (51 ± 12 years; 65% of subjects male; 3.4% had a previous cardiovascular event) and were found to have microalbuminuria (15 to 300 mg/24 hours) on screening. Patients were excluded when the creatinine clearance was 60% higher than the normal age-adjusted value. The mean follow-up was 46 months, and the primary end point was cardiovascular mortality and hospitalisation for cardiovascular morbidity. Patients were randomised to fosinopril 20 mg or matching placebo and to pravastatin 40 mg or matching placebo. Mean cholesterol level was 5.8 ± 1.0 mmol/L, mean systolic/diastolic blood pressure $130 \pm 18/76 \pm 10$ mm Hg, and median urinary albumin excretion 22.8 (15.8 to 41.3) mg/24 hours.

Although fosinopril produced a significant (26%, $P < 0.001$) reduction in albuminuria in 45 subjects (5.2%) and was associated with a trend of decreasing cardiovascular events (HR 0.60; 95% CI 0.33 to 1.10; $P < 0.098$), treatment with pravastatin did not result in a significant reduction in urinary albumin excretion or a reduction in cardiovascular events (HR 0.87; 95% CI 0.49 to 1.57; $P > 0.649$). The authors concluded that in this study, treatment with pravastatin did not result in a significant reduction in urinary albumin excretion or cardiovascular events.

■ 4. UK-HARP-I trial, 2005²⁰

Two studies were designed to establish the biochemical efficacy and to gain more information on the safety of cholesterol-lowering drugs in patients with CKD.

In the first UK Heart and Renal Protection study (UK-HARP-I)²⁰, 448 patients with CKD were randomly assigned in a 2×2 factorial design to the administration of 20 mg of simvastatin daily versus matching placebo, and 100 mg of modified-release aspirin daily versus matching placebo. At the start, 242 patients were predialysis (creatinine level ≥ 1.7 mg/dL), 73 were receiving maintenance dialysis, and 133 had a functioning transplant. Among those with predialysis, renal failure or a functioning transplant at baseline, aspirin did not increase the number of patients who progressed to dialysis therapy (4% versus 3% patients; $P = \text{NS}$) or experienced a greater than 20% increase in creatinine level (34% versus 30%; $P = \text{NS}$).

After a follow-up of 12 months, allocation to 20 mg of simvastatin daily reduced non-fasting total cholesterol levels by 18% (simvastatin, 163 mg/dL versus placebo, 196 mg/dL, $P<0.0001$), LDL levels by 24% (89 mg/dL versus 114 mg/dL; $P<0.0001$), and triglyceride levels by 13% (166 mg/dL versus 186 mg/dL; $P<0.01$). There was no significant effect on high-density lipoprotein cholesterol levels (2% increase; $P=NS$). The simvastatin group did not have a significantly increased risk for abnormal liver transaminases, elevated creatinine kinase, or clinical myopathy. The authors conclude that simvastatin 20 mg/d produced a sustained reduction of approximately 25% in LDL levels, with no evidence of toxicity, and aspirin, 100 mg/d, did not substantially increase the risk for a major bleeding episode.

■ 5. UK-HARP-II trial, 2006²¹

The second UK Heart and Renal Protection study (UK-HARP-II)²¹ was designed to assess the tolerability, safety and biochemical efficacy of ezetimibe (10 mg/d) in combination with simvastatin (20 mg/d). A sample of 203 patients (152 predialysis patients with creatinine levels >1.7 mg/dL, 18 patients on peritoneal dialysis therapy and 33 patients on haemodialysis therapy) were randomly assigned to the administration of simvastatin, 20 mg/d plus ezetimibe, 10 mg/d; or simvastatin, 20 mg daily plus placebo ezetimibe daily.

Six months later, patients taking simvastatin alone observed a 31-mg/dL decrease in nonfasting LDL levels compared with baseline. Use of simvastatin plus ezetimibe produced an additional 18-mg/dL decrease in LDL levels (an incremental 21% reduction; $P<0.0001$). No statistically significant effects of the addition of ezetimibe to simvastatin on triglyceride or HDL levels were observed. Ezetimibe was not associated with liver toxicity and did not impair absorption of fat-soluble vitamins. There were no serious adverse events caused by study treatment.

■ 6. Sandhu S *et al.* systematic review, 2006²²

In 2006 an important systematic review and meta-analysis was published²², including 27 randomised trials of statins (21 with data for eGFR and 20 for proteinuria or albuminuria) which reported kidney

function or proteinuria in 39,704 patients, to assess the effect of statins on change in kidney function and urinary protein excretion. Medline, EMBASE, the Cochrane Central Register of Controlled Trials, conference proceedings, and authors' personal files were searched. The results showed that the use of statins in 21 trials was associated with small reductions in rate of decline of eGFR (WMD 1.22 mL/minute per year; 95% CI 0.44 to 2.00), and that this effect was significant in a subgroup of trials including patients with cardiovascular disease (difference 0.93 mL/minute per year; 95% CI 0.10 to 1.76) but not significant in subgroups with diabetic or hypertensive kidney disease or glomerulonephritis.

In meta-analysis of 20 trials the standardised mean difference for the reduction in albuminuria or proteinuria as a result of statin therapy was significant (0.58 units of SD greater in statin recipients; 95% CI 0.17 to 0.98). The authors conclude that statin therapy seemed to reduce proteinuria modestly and resulted in a small reduction in the rate of kidney function loss, especially in populations with cardiovascular disease.

■ 7. Douglas K *et al.* systematic review, 2006²³

In the same year as the previous one another systematic review was published²³, including 15 randomised placebo-controlled trials with an average duration of 24 weeks with a total of 1,384 patients (11 trials reported albuminuria and 4 trials reported proteinuria). This meta-analysis had some statistical heterogeneity. This was evident only in the group with excretion greater than 300 mg/d (excretion <30 mg/d, $I^2=23\% P=0.27$; excretion 30 to 299 mg/d, $I^2=0\% P=0.64$; excretion ≥ 300 mg/d, $I^2=63\% P = 0.020$). Statin use was associated with reduction in albuminuria or proteinuria in 13 of 15 trials.

The reduction in excretion demonstrated in trials with greater baseline albuminuria or proteinuria was as follows. No reduction (estimated +2%, 95% CI -32% to +35%) for 3 trials with baseline excretion <30 mg/day; 48% reduction (95% CI -71% to -25%) for 6 trials with excretion 30-300 mg/day and 47% reduction (95% CI -67% to -26%) for 6 trials with excretion >300 mg/day. The authors concluded that statins may have a beneficial effect on pathological albuminuria.

■ 8. Post-hoc analysis of the JUPITER trial²⁴

The JUPITER trial²⁹, a study into 17,802 men and women with $\text{LDL} < 130 \text{ mg/dl}$ but elevated C-reactive protein (CRP) ($\geq 2 \text{ mg/l}$) during a median follow-up of 1.9 years (maximum 5 years), demonstrated a 44% reduction in major vascular events and a 20% reduction in all-cause mortality for those allocated to rosuvastatin 20 mg daily as compared with placebo. A secondary analysis of this trial²⁴ evaluated the efficacy of statin therapy in primary prevention among 3,267 individuals with moderate CKD (defined as an eGFR $< 60 \text{ ml/min}/1.73 \text{ m}^2$), comparing cardiovascular and mortality outcomes with patients with baseline $\text{eGFR} \geq 60 \text{ ml/min}/1.73 \text{ m}^2$ ($n=14,528$).

Results showed that when compared with participants with higher eGFR, those with moderate CKD had higher vascular event rates (HR: 1.54, 95% CI 1.23 to 1.92, $P=0.0002$) and that rosuvastatin was associated with a 45% reduction in risk of a composite outcome of myocardial infarction, stroke, hospital stay for unstable angina, arterial revascularization, or confirmed cardiovascular death (HR: 0.55, 95% CI 0.38 to 0.82, $P=0.002$) and a 44% reduction in all-cause mortality (HR: 0.56, 95% CI 0.37 to 0.85, $P=0.005$). Patients had median reductions of LDL and CRP, as well as side effects, similar to the ones with CKD, with a marginal improvement in median eGFR at 12 months (Table II).

The authors concluded that statin therapy with rosuvastatin reduced first cardiovascular events and all-cause mortality among men and women with $\text{LDL} < 130 \text{ mg/dl}$, elevated CRP, and moderate CKD.

■ 9. Navaneethan SD et al. Cochrane SR 2009²⁵

A Cochrane systematic review was published in 2009²⁵ that included 26 randomised placebo-controlled trials evaluating statins in 25,017 adults with

CKD not requiring dialysis. The studies had methodological limitations: unclear or inadequate concealment of allocation in 21 trials; only double masking – patients and investigators – in eight trials; triple masking (patients, investigators and outcome assessors) only in one trial and no use of intention-to-treat analysis in 21 trials.

The results showed that when comparing statins with placebo all-cause mortality was reduced: 7.6% vs. 9.4% (21 trials with 18,762 patients – $p < 0.0001$, NNT=56), with these results primarily from a single large trial with 16,824 patients; cardiovascular mortality was reduced from 4.5% to 5.7% (20 trials with 18,746 patients – $p = 0.00034$, NNT=84), with results primarily from the same single large trial with 16,824 patients and nonfatal cardiovascular events were reduced – 14.5% vs. 18.5% – in analysis of 5 trials with 19,363 patients ($p < 0.00001$, NNT 25).

In this review statins were associated with decreased total cholesterol in analysis of 18 trials with 1,677 patients ($\text{WMD} = -41.5 \text{ mg/dL}$, 95% CI -50 to -34 mg/dL); decreased low-density lipoprotein (LDL) cholesterol in analysis of 16 trials with 1,605 patients ($\text{WMD} = -42.4 \text{ mg/dL}$, 95% CI -50.7 to -34.1 mg/dL, $P < 0.00001$); decreased 24-hour urinary protein excretion in analysis of 6 trials with 311 patients ($\text{WMD} = -0.73 \text{ g/24 hours}$, 95% CI -0.95 to -0.52 g/24 hours, $P < 0.00001$). No significant differences in creatinine clearance were detected in 11 trials with 548 patients. Also, no significant differences in incidence of rhabdomyolysis, elevated liver enzymes or withdrawal rates due to adverse events were found.

■ 10. SHARP trial²⁶

The largest clinical trial published to date directly modulating lipids in CKD was the SHARP (Study of Heart and Renal Protection) trial, performed in 380

Table II

Outcomes among those allocated to rosuvastatin or placebo ($\text{eGFR} < 60 \text{ ml/min}/1.73 \text{ m}^2$)

	Rosuvastatin group		Placebo group		HR (95% CI)	<i>p</i> Value
	n	rate	n	rate		
Primary end point	40	1.08	71	1.95	0.55 (0.38–0.82)	0.002
All-cause mortality	34	0.85	61	1.53	0.56 (0.37–0.85)	0.04

hospitals in eighteen countries²⁶. The clinical question was the efficacy and safety of simvastatin plus ezetimibe in patients with chronic kidney disease (32.6% on dialysis). It was a randomised placebo-controlled trial with concealed allocation, triple blinding (patients, clinicians, and outcome adjudicators), with a follow-up ≥4 years (median 4.9 years for survivors). The sample included 9,270 patients with a mean age of 62 years (63% men) who had CKD, defined as a previous serum or plasma creatinine level ≥1.7 mg/dL in men or 1.5 mg/dL in women and no previous acute myocardial infarction or coronary revascularisation. Patients with low compliance with placebo during the six-week run-in period were excluded. Patients were randomly allocated to simvastatin, 20 mg/day, plus ezetimibe, 10 mg/day (n=4,650), or placebo (n=4,620). 886 of 1,054 patients who were initially randomly assigned to simvastatin alone were re-randomised after one year to simvastatin plus ezetimibe or placebo, and are included in the samples above.

The outcomes were: 1) first major atherosclerotic event (nonfatal AMI or coronary death, non-haemorrhagic stroke, or arterial revascularisation excluding dialysis access procedures); 2) major vascular event (nonfatal AMI or any cardiac death, any stroke, or arterial revascularisation excluding dialysis access procedures), and 3) end stage renal disease (ESRD).

Final follow-up was 98% (intention-to-treat analysis). The table shows that simvastatin + ezetimibe reduced risk of major atherosclerotic events and major vascular events more than placebo. In patients who were not receiving dialysis at the start of the trial (n=6,247), groups did not differ for ESRD.

Comparing ezetimibe/simvastatin combination vs. placebo, nonfatal myocardial infarction was 2.9% versus 3.4% (not significant), coronary heart disease

mortality was observed in 2% vs. 1.9% (not significant), non-haemorrhagic stroke in 2.8% vs. 3.8% (p = 0.01, NNT 100) and revascularisation in 6.1% vs. 7.6% (p = 0.0036, NNT 67). The conclusions of this study were that the combination simvastatin plus ezetimibe reduced risk for major atherosclerotic events in patients with CKD.

CONCLUSIONS

The best published studies show that CKD is a powerful risk factor for cardiovascular disease, with event rates which remained 25% higher than those who had normal kidney function. Our paper confirms the benefit of statins in patients with moderate CKD.

In short, there are a series of statements that can be made concerning the effects of statins in patients with CKD not on dialysis:

- The combination ezetimibe/simvastatin reduces AMI, non-haemorrhagic stroke and revascularisation in these patients, and less than 50 patients need to be treated over four years to avoid a CV event.
- The combination ezetimibe/simvastatin reduces LDL levels more than simvastatin alone.
- Treatment with atorvastatin plus ACE inhibitors or ARBs may reduce proteinuria and the rate of progression of kidney disease, proteinuria and hypercholesterolaemia.
- Pravastatin was associated with slower renal function decline than placebo in patients with moderate reduced GFR and proteinuria.

Table III

Lipid modulation in CKD

	Placebo group	Simvastatin + ezetimibe group	RRR	ARR	NNT
Major CV (AMI + stroke + CV mortality + revascularisation)*	13%	11%	16	2,1	48
Major vascular event (nonfatal AMI or any cardiac death, any stroke, or arterial revascularisation)	18%	15%	17	3	33
ESRD	35%	34%	-	-	-

*calculated from paper. RRR=relative risk reduction; ARR=absolute risk reduction; NNT= number needed to treat.

- Simvastatin has similar effects on total cholesterol, LDL and triglyceride in CKD patients than in patients with normal kidney function.
- Statin use is associated with reduction in albuminuria or proteinuria.
- Statin therapy with rosuvastatin reduced first cardiovascular events and all-cause mortality among men and women with low LDL, elevated CRP and moderate CKD.
- Pravastatin may not be superior to usual care in preventing end-stage renal disease.
- Addition of atorvastatin to angiotensin-converting enzyme inhibitor or angiotensin receptor blocker may slow progression of renal disease.

Conflict of interest statement. None declared.
